Tipping Points and Business-as-Usual in a Global Carbon Commons

Rodrigo Harrison* and Roger Lagunoff†

July 12, 2015‡

Abstract

This paper formulates a dynamic model of global carbon consumption in the absence of an effective international agreement. Each period, countries extract carbon from the global ecosystem. A country’s output depends both on its carbon usage and on “stored carbon” in the ecosystem. We characterize Business-as-usual (BAU) equilibria as smooth, Markov Perfect equilibrium profiles of carbon usage across countries. In any BAU equilibrium, the desired mix of extracted versus stored carbon by each country is determined by its stochastically evolving output elasticities with respect carbon input.

A non-concavity in the carbon dynamic creates the possibility that global system reaches a tipping point, a threshold level of stored carbon stock below which the global commons collapses, spiraling downward toward a steady state of marginal sustainability. We show that if, in any BAU equilibrium, the profile of carbon factor elasticities reaches a high enough threshold, a tipping point will be breached. Ironically, the countries actually accelerate their rates of carbon usage the closer the carbon commons comes to tipping. Even so, there remains a time span (a “negotiation window”) in which a collapse may be averted if the countries agree to implement the socially efficient profile of carbon usage.

1 Introduction

Human consumption is based on carbon usage. Alarmed by increases in anthropogenic GHGs, many scientists and policy experts focus on finding an effective international response to limit carbon emissions.\(^1\)

This paper formulates a dynamic model of global carbon consumption in the absence of such a response. Our objective is to understand the strategic incentives of nations in a “business-as-usual” (or “BAU” from here on) scenario. What are the long run implications of BAU? How does it compare with socially efficient usage? Are outcomes under BAU sustainable or is economic collapse inevitable? What determines the transition, if any, from sustainability to collapse?

To make sense of the last few questions in particular, our model integrates a strategic model of emissions into a nonlinear dynamic model of carbon. A key feature of this model is that consumption and economic output may collapse and shrink if a key state variable falls below some critical threshold — a tipping point.

Tipping points are commonly discussed and modeled in the earth science literature, a sample of which includes Lenton, et al. (2008), Kerr (2008), Rockstrom, et al. (2009), Anderies, et al. (2013), and Steffen, et al. (2015). Most of these posit nonlinear dynamical systems that describe a safe operating space (SOS) for humanity, i.e., a region consisting of levels of methane and \(CO_2\) concentrations, degrees of biodiversity, and so on, that sustains human innovation, growth, and development. Tipping points are typically described as the planetary boundaries of these regions (see Rockstrom et al. (2009)).

The earth science models contain a detailed account of the different forms of carbon mass and their movements throughout the carbon cycle. However, human incentives are not modeled explicitly. By contrast, the present paper posits a much simpler physical model of carbon. We abstract, for instance, from complicated marine-atmospheric diffusion processes and plant photosynthesis and respiration. The upside is that the model offers a rich and tractable characterization of incentives.

Our particular focus on strategic incentives of nations distinguishes our work from the burgeoning literature that integrates GE economies with tipping models of climate dynamics. These include IAMs (integrated assessment models) of Nordhaus (2006, 2007, 2008) and Lemoine and Traeger (2014), Hope (2006), Stern (2006), and Cai, Judd, and Lontzek (2012), all of whom incorporate the possibility of abrupt changes in the earth’s climate and ecosystem.\(^2\)

1. e.g., IPCC Fourth Assessment Report: Climate Change 2007.
2. See also Krusell and Smith (2009), Acemoglu et al. (2012), and Golosov et al. (2014) for useful quantitative assessments of carbon taxation and cap and trade policies.
A study of the incentives of state actors is, to us, a sensible addition to the IAM literature since the most critical policy choices are made by large, powerful nations with divergent interests.

We therefore posit a model in which each country produces a composite consumption good for its citizens. Production depends both on a carbon-based input and on the renewable ecosystem. The ecosystem is an open access source of stored carbon from which countries can freely extract. While each country’s carbon extraction is essential for its own production, the global extraction depletes an ecosystem also essential to the production process. Some preservation of the ecosystem and its repository of stored carbon is, therefore, beneficial for purely economic reasons (Section 2.1 further elaborates).

The model builds on the common pool framework of Levhari and Mirman (LM) (1980), Cave (1987), Dutta and Sundaram (1993), Sorger (1996), Finus (2001), Barrett (2003), Dutta and Radner (2004, 2006, 2009), and Battaglini and Harstad (2012), all of whom examine strategic incentives in dynamic games with a commons or with climate externalities. The over-depletion problem arising here echoes the “tragedy of the commons” theme running through these models. Our emphasis on tipping point dynamics presents a distinct set of challenges for the common pool problem.

The carbon dynamics in the model distinguish between emitted and “stored” (non-atmospheric) carbon. The latter is summarized by a carbon resource stock $\omega_t$ at each date $t$ representing all usable sources of non-atmospheric carbon in the global ecosystem. The stock $\omega_t$ may be thought of as known reserves of “stored” or “preserved” carbon in biomass, soil, or fossils. Once extracted, carbon is used in the production process and emitted into the atmosphere. The simple distinction between stored and emitted carbon is the basis for all dynamic changes in the model.

Each country’s desired mix of stored and extracted carbon is determined by its relative output elasticities. Countries with relatively high output elasticities of extracted carbon prefer to extract more than countries with low elasticities. The elasticities are assumed to evolve stochastically, and the country-specific shocks to these may be serially correlated. This assumption captures a common feature in studies of climate change: both environmental costs and factor composition vary over time, are difficult to forecast, and often vary widely across countries. Heterogeneity reflects variation in geographic, demographic, and politico-economic influences.\footnote{Burke, et. al. (2011) find, for example, widely varying estimates of the effect of climate change on US agriculture when climate model uncertainty is taken into account. Desmet and Rossi-Hansberg (2014) document substantial cross country variation in a calibrated model of spatial differences in welfare losses across countries due to global warming.} The profile of country-specific carbon elasticities, together with the carbon stock constitute the state variables of the system.
The driving force of the model is a low-end instability in the law of motion for carbon. When $\omega_t$ is large enough, dynamic forces of release and recapture produce a stable carbon cycle. A low enough stock, however, can destabilizes the cycle leading to a collapse — a tipping problem. The tipping point at which this occurs is endogenously determined in a business-as-usual (BAU) equilibrium, a smooth Markov Perfect equilibrium profile of carbon usage across countries. The main results characterize BAU equilibria, endogenous tipping points, and the incentives of countries in the face of a tipping threat.

Sakamoto (2014) also studies BAU equilibria in a tipping model. In his model, a given resource threshold triggers a change in the likelihood of a regime switch, i.e., a switch from a high growth state to a low growth one. Strategic play determines whether the threshold is breached.

In the present model the resource thresholds — in our case tipping points — themselves arise endogenously from strategic play. In turn, strategic choices depend on exogenous technical change. Thus, the “deep” parameters that determine tipping here are technological: the factor elasticities determining the mix of extracted and stored carbon. The tipping points separate regions of $\omega_t$ in which collapse will never occur (the safe operating space (SOS)) from regions of possible collapse. Regions of possible collapse can be distinguished from regions of inevitable collapse. Consequently, the mechanism produces a schematic consistent with the planetary boundaries framework of Rockstrom et al. (2009) and Steffan, et al. (2015) and is displayed below.\(^4\)

\[
\begin{align*}
\text{collapse} & \quad | \quad \text{uncertain collapse,} \\
& \quad | \quad \text{unsafe operating space} & \quad | \quad \text{safe operating space} \\
\omega^{\text{tip}} & \quad | \quad \omega^{\text{safe}}
\end{align*}
\]

In this schematic, the tipping points are the boundaries of the support of an equilibrium distribution. This distribution describes the probability of collapse starting from any given stock. We find parametric configurations to support both SOS and collapse, although the historical pattern suggests a troubling trend toward the latter.

Our results show the following. First, a global economy in a BAU equilibrium can remain in SOS if elasticities of carbon usage remain low. If, however, the carbon factor elasticities become large enough and remain so over a long enough span of time, the BAU equilibrium will eventually breach a tipping point, precipitating a collapse.

Second, countries actually accelerate their rates of carbon usage the closer the carbon commons comes to tipping. By contrast, countries are more cautious the further they are from tipping. The intuition is reminiscent of the Green Paradox (Sinn (2013)) which posits that resource extraction accelerates if more stringent regulations are expected in the future. Under strategic competition for the carbon commons, the marginal continuation value to a country of preserving the carbon stock vanishes if it anticipates a high enough likelihood of tipping due to the strategic play of others.

This result is accentuated by heterogeneity in elasticities across countries. Countries with either very high or very low carbon factor elasticities have larger output than those with intermediate elasticities. This means that even as the global commons reaches a tipping point, the leading carbon emitters are not the first to suffer consequences of an accelerated decline.

Third, the BAU equilibrium generates lower aggregate output and higher carbon use each period than the extraction plan chosen by a social planner. This is a standard result in non-tipping models of the commons. We show that it remains true with tipping. Moreover, the relative difference between the BAU and socially optimal paths of aggregate carbon stock grow over time. Unlike most commons models, some countries might actually use less carbon under BAU.

Fourth, we show that collapse may be avoided, but only if the international community moves away from business-as-usual and toward a socially optimal extraction regime. Specifically, because the tipping point is determined endogenously by equilibrium extraction rates, even if the equilibrium tipping point is breached there is still some time (a “negotiation window”) in which a collapse may be averted if the countries agree to implement the optimal plan.

The upshot is that an effective international agreement provides an additional buffer against large shocks to the carbon stock. This suggests a somewhat more optimistic scenario than the other results. This is clearly contingent, however, on whether countries can achieve such an agreement.5

---

2 A Tipping Model of Carbon Usage

2.1 An Overview

This section lays out a rudimentary model of carbon usage. The model consists of an infinite horizon global economy with $n$ countries. Each country makes use of an essential resource — carbon — each period. Carbon is extracted from a carbon-based commons which we refer to as the “global ecosystem.”

The framework is reminiscent of the classic common pool model of Levhari and Mirman (LM) (1980). In the LM model, identical users choose how much of a depletable, open access resource to consume each period. Examples include fisheries or forestry. There are no direct costs or externalities from usage. More importantly there is no tangible constraint on consumption/production until the resource stock literally hits zero. Conservation is thus valued in LM only for instrumental reasons: preserving the stock allows one to smooth consumption.

By contrast, we analyze a production technology where the renewable ecosystem enters as an input. This means that, unlike a pure commons, there are tangible impediments to production even when the stock is not fully depleted. As a result, there are incentives to conserve even if there is no threat whatsoever of full depletion. We further modify the model by (1) introducing heterogeneous shocks that affect each country’s desired mix of productive inputs, and (2) positing a carbon dynamic with a low-end non-concavity capable of tipping the system.

Some features of the setup should be clarified at the outset. First, one could argue that accumulation of geological carbon is a long term process and should therefore be considered separate from the ecosystem. Our inclusion of it in the stock is based on evidence that extraction of fossil fuels can deplete the ecosystem (Rockstrom, et al. (2009)). Fracking, strip-mining, oil drilling all involve potential depletion of biomass or limits on its growth. Stored carbon stock represents a “flip side” of carbon emissions in our model, and so avoiding emissions is equivalent to preserving the stock — including geological carbon.

Second, one might observe that fossil fuels are not open access; its distribution around the world is non-uniform. When all forms of emittable carbon are taken into account, however, open access can be defended as a fair approximation. Countries like Brazil and Tanzania have large rain forests and agricultural production. Other countries like Russia and Saudi Arabia extract fossil fuels. Asymmetries in access are also incorporated indirectly by assuming heterogeneous technologies across countries.
2.2 Output and Carbon Extraction

Countries make inter-temporal strategic decisions regarding how much carbon to extract and use. Country \( i \)’s (\( i = 1, \ldots, n \)) carbon extraction in date \( t \) is denoted by \( c_{it} \). Let \( C_t = \sum_i c_{it} \) represent the level of global carbon consumption at \( t \). Consumption of \( C_t \) units of carbon produces \( C_t \) units of emissions, and so the two terms are sometimes used interchangeably. The global consumption \( C_t \) is consumed from a stock \( \omega_t \) that represents all usable sources of non-atmospheric carbon in the global ecosystem. The stock \( \omega_t \) may be thought of as known reserves of “stored” or “preserved” carbon in soil, biomass, or fossils. Once extracted, carbon is emitted into the atmosphere. The simple distinction between stored and released carbon forms the basis for all dynamic changes in the model.

A composite good \( y_{it} \) for each country represents the output consumed by the representative citizen from country \( i \) at date \( t \). The production of \( y_{it} \) depends on both extracted carbon and the carbon-based global ecosystem according to the production technology

\[
y_{it} = c_{it}^{\theta_{it}} (\omega_t - C_t)^{1-\theta_{it}}.
\]

In (1), \( \theta_{it} \in [0, 1] \) is the output elasticity of extracted carbon, while \( 1 - \theta_{it} \) is the output elasticity of the global ecosystem net of aggregate consumption. Countries with larger \( \theta_{it} \) in date \( t \) will typically extract and emit more carbon, other things equal.

The long run payoff to the representative citizen from country \( i \) for consuming \( y_{it} \) at each date \( t \) is

\[
\sum_t \delta^t u(y_{it})
\]

with \( u \) strictly, differentiably concave, and \( u' \to \infty \) as \( y_{it} \to 0 \). The main equilibrium characterization results will assume \( u(y_{it}) = \log(y_{it}) \). All countries discount the future according to \( \delta \).

The formulation accounts for the fact that all countries’ economies have carbon requirements, but production also requires that countries draw upon a viable ecosystem. Recall that the stored carbon stock represents a “flip side” of carbon emissions, and so the assumption of that the stored stock is a productive input is equivalent to modeling carbon emissions as a GDP-reducing cost.

The model, moreover, builds in correlated shocks to the relative elasticities. The elasticities are assumed to vary both over time and between countries, the latter reflecting the fact that both benefits and costs of extraction differ across countries. Warmer average temperatures resulting from GHG emissions are viewed differently in Greenland than in Sub-saharan Africa. Time variation comes from the fact that
countries may be hit with serially correlated shocks. The shocks capture the unpredictability of technological change and the persistence of climatic change within each country.

A type profile in date \(t\) is a vector
\[
\theta_t = (\theta_{1t}, \theta_{2t}, \ldots, \theta_{nt}),
\]
and is publicly observed at the beginning of each period \(t\). Let \(\theta^t = \{\theta_0, \theta_1, \ldots, \theta_t\}\) be the history of realized type profiles up to and including date \(t\), and let
\[
\theta^\infty = \{\theta_0, \theta_1, \ldots, \theta_t, \ldots\}
\]
the infinite time path of elasticity profiles.

Fixing the initial profile \(\theta_0\), the profile \(\theta_t\) is assumed to evolve according to a stationary, though not necessarily ergodic, Markov process \(\pi(\theta_t|\theta_{t-1})\). In what follows, “almost everywhere” will refer to the paths \(\theta^\infty\) in the probability space \((\Theta^\infty, \mathcal{F}, P)\) such that \(\pi\) is the Markov density associated with a filtration \(\{\mathcal{F}_t\}\) on the space \((\Theta^\infty, \mathcal{F}, P)\). We allow for \(\pi\) to exhibit both persistence across time and correlation of carbon elasticities across countries.

### 2.3 Carbon Stock Dynamics

We introduce a law of motion which, in the absence of human consumption (i.e., \(C_t = 0\)), will balance the dynamic forces of release and recapture of carbon through sequestration to produce a stable carbon cycle if the stock \(\omega_t\) is not too low. The law of motion, however, also contains a non-concavity that can destabilizes the cycle if the stock is low enough. Expressed formally, the ecosystem evolves according to:

\[
\omega_{t+1} = \begin{cases} 
A(\omega_t - C_t - b)\gamma & \text{if } A(\omega_t - C_t - b)\gamma \geq F \\
F & \text{otherwise}
\end{cases}
\]  

(3)

with the initial stock fixed at some level \(\omega_0\). By assumption, \(\gamma < 1\) which allows for depreciation (e.g., plant respiration), while \(A > 1\) which allows for accumulation due to natural reabsorption (e.g., plant photosynthesis). For now the parameter \(A\) is assumed to be constant but the model can be generalized to allow for a time-varying ergodic process \(\{A_t\}\), in which case there is a stable carbon cycle if the stock is large enough.\(^6\) A transversality condition entails a joint restriction \(\delta \gamma < 1\).

\(^6\)An even richer model would allow \(A\) to depend on the existing stock. For tractability, however, we assume it is fixed and exogenous.
The parameter $b$ describes the exogenous “off-take”, the subtraction of carbon from the stock that is independent of human decisions. It can be interpreted as a lower bound below which natural recapture or sequestration cannot occur. When $b > 0$ the carbon-based ecosystem can collapse and shrink if the stock falls below some critical carbon threshold — a tipping point — a concept explicitly defined and characterized in Section 3.2. Figure 1 illustrates the dynamic in (3) (for illustrative purposes, $C_t$ is held constant in the Figure). There are three fixed points, one of which is unstable. In a non-stochastic version of the model, the unstable fixed point would correspond to an endogenously determined “tipping point.” In this case, $F$ represents an “environmental poverty trap” since a stock that reaches the carbon floor $F$ remains stuck there forever.\footnote{The figure is canonical under a parametric restriction. Specifically, all fixed points of $\omega_{t+1} = A(\omega_t - C_t - b) \gamma$, if any exist, must lie above $F$. A sufficient condition for this is to require $b$ sufficiently large such that any stock $\omega$ satisfying to $\omega = A(\omega - b) \gamma$ (fixing $C_t = 0$) must lie above $F$.} Critically, the preserved stock can grow only if it exceeds the unstable fixed point as shown in Figure 1.

When $F > 0$ carbon stocks are never fully depleted. This assumption is a largely matter of convenience.\footnote{Specifically, because $u = -\infty$ at zero, a floor $F > 0$ rules out full depletion, thus avoiding the limit at $\omega_t = 0$.} Instead, the exogenous off-take $b > 0$ is the critical parameter because there is no tipping problem if $b = 0$ (a fact established later in Section 3).
For this reason, the model with \( b > 0 \) will be referred to as the “tipping model” — as distinct from the benchmark no-tipping case \( (b = 0) \).

The dynamic in (3) is not intended to be a literal description of an earth system. Rather, we view it as a tractable heuristic that incorporates a local instability at the low-end of the carbon stock. Specifically, the carbon dynamic allows for growth, depreciation, and/or sudden collapse to the stock, depending on parameters.

Let \( c_t = (c_{1t}, \ldots, c_{nt}) \) denote the date \( t \) profile of resource consumption (and emissions). The entire dynamic path profile of resource consumption is the given by

\[
c = \{c_t\}_{t=0}^\infty
\]

A consumption path \( c \) is feasible if it is consistent with the dynamic constraint (3) and \( C_t \leq \omega_t - b \) at each date \( t \).

Overall, the model presents a simplification of the geophysical dynamics of carbon. It nevertheless captures what Cai, et al. (2012, p.2) argue are two critical features that should be included in a reasonable representation of tipping. Namely, “(i) a fully stochastic formulation of abrupt changes, and (ii) a representation of the irreversibility” of the collapse. Regarding (ii), the law of motion in Equation (3) converges to a low but finite steady state \( F \) whenever the carbon stock falls below a critical “tipping” point. The fact that the low steady state is independent of human activity is roughly consistent with simulations by Hansen et. al (2013), demonstrating a “soft” or “low-end” runaway greenhouse effect. Their simulations “indicate that no plausible human-made GHG forcing can cause an instability and runaway greenhouse effect” in which extreme, amplified feedbacks fully dissipate the stored carbon stock and evaporate all planetary surface water — as believed to have happened on Venus.

3 The Business-As-Usual Equilibrium

In any period, the state of the global carbon economy is summarized the pair \( (\omega_t, \theta_t) \) consisting of the ecosystem and the elasticity profile. A Markov-contingent plan is a state-contingent profile

\[
c^*(\omega_t, \theta_t) = (c^*_1(\omega_t, \theta_t), \ldots, c^*_n(\omega_t, \theta_t))
\]

that specifies each country’s usage \( c^*_i(\omega_t, \theta_t) \) as a function of the state \( (\omega_t, \theta_t) \). The corresponding aggregate consumption is \( C^*(\omega_t, \theta_t) = \sum_i c^*_i(\omega_t, \theta_t) \).

The long run payoff of a Markov-contingent plan \( c^* \) to the representative citizen
in country $i$ may be expressed as

$$U_i(\omega_t, \mathbf{c}_t^*, \theta_t) \equiv E \left[ \sum_{\tau=t}^{\infty} \delta^{\tau-t} u \left( (c^*_\tau(\omega_{\tau}, \theta_{\tau}))^{\theta_{\tau}} (\omega_{\tau} - C^*_\tau(\omega_{\tau}, \theta_{\tau}))^{1-\theta_{\tau}} \right) \bigg| \omega_t, \theta_t \right]$$  \hspace{1em} (4)

A Markov Perfect equilibrium (MPE) is a Subgame Perfect equilibrium in which each country’s strategy is a Markov-contingent plan.$^9$ The MPE is often interpreted as a “business-as-usual” benchmark since it represents a scenario that prevails in the absence of any agreement or coordination among the participants. The MPE requires no special coordination, no monitoring beyond the initial quota, and no explicit sanctions.$^{10}$ The definition is fairly standard in the dynamic common pool literature (e.g., Dutta and Radner (2009)).

We further restrict attention to smooth MPE, that is, Markov-contingent plans that are both Subgame Perfect and smooth functions of the state (smooth everywhere except possibly at the floor $F$). This restriction rules out certain MPE that use discontinuities in the state to create triggers on which participants can tacitly coordinate.

Consequently, we refer to any such MPE as a Business-as-usual (BAU) equilibrium. In any BAU equilibrium, country $i$’s Markov-contingent plan $c^*_i(\omega_t, \theta_t)$ must maximize its long run payoff from date $t$, given the carbon dynamic in Equation (3) and production technology (1), and given any past history of consumption and elasticity profiles.

Let $\omega^*_t(\omega_t, \theta_t)$ denote the BAU equilibrium law of motion when (3) is evaluated at $c^*(\omega_t, \theta_t)$. Iterating forward, $\omega^{*t+s}(\omega_t, \theta^{t+s-1})$, $s = 0, 1, 2 \ldots$ denotes the equilibrium path from $\omega_t$.$^{11}$ Depending on trends in elasticities over time, both growth or contraction in output and carbon stock can occur in equilibrium.

$^9$In any MPE each country’s Markov-contingent plan $c^*_i$ maximizes $U_i(\mathbf{c}^*, \omega_t, \theta_t)$ given $c^*_{-i}$ in any state $(\omega_t, \theta_t)$ over the set of full history-contingent consumption plans. For brevity, we omit the specification of full history contingent strategies. Payoffs corresponding to infeasible paths must be formally defined as well. For our purposes, the simplest approach is to define the payoff on the extended real line, setting flow payoffs equal to $-\infty$ whenever $C_t \geq \omega_t + b$.

$^{10}$Without the Markov restriction, a version of a Folk Theorem can be applied (see, for instance, Dutta (1995) for a general statement), and efficient plans can be implemented by international coordination on the appropriate punishments.

$^{11}$This path of carbon stock is defined inductively by

$$\omega^{*t+1}(\omega_t, \theta^t) = \omega^*_{t+1}(\omega_t, \theta_t), \quad \omega^{*t+2}(\omega_t, \theta^{t+1}) = \omega^*_{t+2}(\omega^{*t+1}(\omega_t, \theta^t), \theta_{t+1}), \quad \ldots$$

$$\ldots \quad \omega^{*t+s}(\omega_t, \theta^{t+s-1}) = \omega^*_{t+s}(\omega^{*t+s-1}(\omega_t, \theta^{t+s-2}), \theta_{t+s-1}), \quad \ldots$$
3.1 Euler equation

Using the parameterization \( u(y_{it}) = \log(y_{it}) \) in (4), the BAU equilibrium consumption \( c^*_i(\omega_t, \theta_t) \) may be found as a solution to the Bellman equation

\[
U_i(\omega_t, c^*, \theta_{it}) = \max_{c_{it}} \left\{ \theta_{it} \log c_{it} + (1 - \theta_{it}) \log(\omega_t - C_t) + \delta E \left[ U_i(\omega_{t+1}, c^*, \theta_{it+1}) \right| \omega_t, \theta_{it} \right\}
\]

subject to (3) after for every state \((\omega_t, \theta_t)\).

To calculate the BAU it is simpler to work with extraction rates rather than levels. The extraction rate \( e_{it} \) is defined implicitly by \( c_{it} = e_{it} \omega_t \). Denote the global extraction rate by \( E_t = \sum_i e_{it} \).

In the subsequent analysis, we also employ the following notation. Let \( 1^*_{(\omega_t, E_t)} \) be an indicator function taking value “1” whenever \( A(\omega_t(1 - E_t) - b)e^\gamma > F \), and taking value zero otherwise. The indicator registers a value of “1” whenever the carbon floor is not reached next period.

Our first result shows that the BAU equilibrium solves a system of Euler equations in extraction rates. Each Euler equation is derived by applying the usual Envelope theorems to the first order conditions associated with (5). The Euler equations are given by

\[
\frac{\theta_{it}}{1 - \theta_{it}} - \frac{1 - \theta_{it}}{1 - E_t} = \text{net marginal benefit of extraction to country } i \text{ in per. } t
\]

\[
= \frac{\delta \gamma \omega_t}{\omega_t(1 - E_t) - b} \left\{ 1 + E \left[ \left( \frac{\theta_{it+1}}{e_{it+1}} - \frac{1 - \theta_{it+1}}{1 - E_{t+1}} \right) (1 - E_{t+1}) \right| \omega_t, \theta_{it} \right\} 1^*_{(\omega_t, E_t)} \text{ marginal cost of extraction}
\]

A complete derivation of (6) is contained in the Appendix. Equation (6) equates country \( i \)’s marginal extraction benefit (MEB), as measured by its net present benefit in terms of period \( t \) flow payoff, with its marginal extraction cost (MEC) as measured by the loss of stored carbon used for maintaining the ecosystem and for future extraction opportunities. Generally, the equation system in (6) yields no closed form solution and is necessary but not sufficient to characterize BAU equilibria.
Nevertheless, any BAU equilibrium must generate a forward solution to the right-hand side of (6). The result below characterizes BAU equilibria as solutions to the system of Euler equations when the forward solution to the MEC is given explicitly.

Proposition 1 Let $c^*$ be a business-as-usual (BAU) equilibrium. Then $c_i^*(\omega_t, \theta_t) = e_i^*(\omega_t, \theta_t) \omega_t$ for each $i$ and $t$, where $e_i^*(\theta_t, \omega_t)$, country $i$’s equilibrium extraction rate, is an implicit solution of the system of equations

$$\frac{\theta_{it}}{e_i^*(\omega_t, \theta_t)} - \frac{1 - \theta_{it}}{1 - E^*(\omega_t, \theta_t)} = G^*(\omega_t, \theta_t) \equiv E \left[ \sum_{\tau=0}^{\infty} \frac{(\delta \gamma)^{t+s}}{1 - E^*(\omega_t, \theta_t)} \prod_{s=0}^{t} \left( \frac{\omega^{*t+s}(\omega_t, \theta^{t+s-1} - E^*(\omega_{t+s}, \theta_{t+s}))}{\omega^{*t+s}(\omega_t, \theta^{t+s-1} - E^*(\omega_{t+s}, \theta_{t+s})) - b} \right) 1_{\{\omega_{t+s}, e_{t+s}^*\}}(\omega_t, \theta_t) \right]$$

for each country $i$, where $E^*(\omega_{t+s}, \theta_{t+s}) = \sum_j e_j^*(\omega_{t+s}, \theta_{t+s})$, a BAU equilibrium aggregate extraction rate in period $t+s$.

Proposition (1) characterizes the Euler equations of individual countries in a BAU equilibrium. The proposition shows that country $i$’s consumption/emissions in a BAU equilibrium is increasing in its resource elasticity and decreasing in the effective discount factor $\delta \gamma$. The forward solution to the marginal extraction cost is denoted by $G^*(\omega_t, \theta_t)$. It is the same for all countries. The cost is expressed in terms of the ratio of post-consumption stock each period to the post-consumption stock net of $b$.

Because the marginal extraction cost $G^*$ is borne in future periods, it isn’t surprising that it increases in the effective discount factor $\delta \gamma$. The response of $G^*$ to variations in other variables is, however, more subtle.

Holding fixed all other countries’ rates at the equilibrium level, the MEC $G^*$ is not generally increasing in country $i$’s extraction rate $e_{it}$. Such a function is expressed in Figure 2. When the current stock $\omega_t$ is sufficiently large and $i$’s extraction is low, then the constraints implied by $1_{\{\omega_{t+s}, e_{t+s}^*\}}$ do not bind, in which case then marginal cost is increasing in $e_i$ as one might expect.

Yet, if $e_i$ is large enough, then one or more of the constraints are very likely to bind in the near future in which case the marginal cost $G^*$ may, in fact, decrease in $e_i$. The logic is as follows. If $e_i$ is large, then next period’s carbon stock $\omega_{t+1}$ is likely to hit the carbon floor $F$. When countries are certain that it will, then they anticipate that their date $t$ decisions can have no effect on future stocks. But if, by cutting back extraction in $t$, country $i$ can lower this likelihood of hitting the floor in $t+1$, then doing so will extend the expected time horizon over which its date $t$ extraction affects future stocks. These incentives in the presence of tipping are explored in Section 3.3.
Marginal extraction cost (MEC)

Marginal extraction benefit (MEB)

Figure 2: Euler equation
The Proposition characterizes Euler equations for a given BAU equilibrium, but does not establish existence of such equilibria. In an external appendix, an existence result is obtained in a robust class of parameters. Below we construct an explicit BAU equilibrium in closed form whenever $b = 0$ (the case of no-tipping).

**The no-tipping special case.** When $b = 0$, the BAU forward solution in (7) reduces to $G^*(\omega_t, \theta_t) = \frac{\delta_t}{(1-\delta)(1-\varepsilon_t)}$. Thus the no-tipping model admits a simple closed form solution for the BAU equilibrium:

$$c^*_i(\omega_t, \theta_t) = \bar{e}_i(\theta) \omega_t$$

where $\bar{e}_i(\theta)$, $i$’s extraction rate, is independent of the stock and is given by

$$\bar{e}_i(\theta) = \frac{\theta_i (1-\gamma \delta)}{1 - \theta_i (1-\gamma \delta)}$$

The derivation of $c_{it}$ in Equation (8) can be obtained directly from the Euler equation in the Proposition.

Observe that if $\theta_{it} = 1$ for all $i$ and $t$ then the equilibrium coincides with the Levhari-Mirman (LM) (1980) fish war model as a special case. In their model, $\theta_{it} = 1$ and $b = F = 0$ for all $i$ and $t$. In other words, if there is no tipping problem, no direct value from preserving the ecosystem, and no heterogeneity, in that value, then the BAU equilibrium coincides with the one calculated in LM.\(^{13}\)

Even without tipping, the carbon externality has both aggregate and distributional effects that are not present in the standard common pool problem. Extraction rates exhibit cross-sectional dispersion in which countries with either very high or very low resource elasticities have larger consumption than those with intermediate elasticities. This is due to the fact that a country’s output $y^*_i(\omega_t, \theta)$ that is $U$-shaped in $\theta_{it}$, ceteris parabibis. The $U$-shape also helps explain why reversing course is problematic: starting from a high elasticity $\theta_{it}$, as a country’s carbon footprint recedes, output must initially fall before growth is possible again.

\(^{12}\)See faculty.georgetown.edu/lagunofr/BAU4-External-Appendix.pdf.

\(^{13}\)Namely, for all $i$ and $t$,

$$c^*_{it}(\theta = 1) = \frac{(1-\gamma \delta)}{1 - \frac{(1-\gamma \delta)}{1-(1-\gamma \delta)n}} \omega_t = \frac{(1-\gamma \delta)}{n(1-\gamma \delta) + \gamma \delta} \omega_t.$$
3.2 Tipping Points and Collapse

Notice from Figure 1 that when \( b > 0 \) there is a possibility that the stock can depreciate down to the floor \( F \). More precisely, the global commons in a BAU equilibrium will be said to *collapse under BAU at stock* \( \omega_0 \) if the equilibrium path \( \{\omega^* t\} \) of carbon stock converges to \( F \) for almost every path \( \theta^\infty \) of elasticity profiles. That is, the commons collapses at \( \omega_0 \) if

\[
\lim_{t \to \infty} \omega^{*t}(\omega_0, \theta^{t-1}) = F \quad \text{a.e. } \theta^\infty
\]

More generally, let

\[
\mu(\omega_0) = P \left( \left\{ \theta^\infty : \lim_{t \to \infty} \omega^{*t}(\omega_0, \theta^{t-1}) = F \right\} \right)
\]

denoting the probability of collapse. In the no-tipping model, \( \mu(\omega_0) = 0 \) if \( \omega_0 > 0 \). At the other extreme, if the commons collapses the stock spirals downward toward threshold \( F \). A tipping point is therefore the largest stock from which the collapse must occur. Specifically, a *tipping point* is a carbon stock \( \omega^{\text{tip}} \) satisfying

\[
\omega^{\text{tip}} = \sup \{ \omega_0 : \text{the commons under BAU collapses at } \omega_0 \}
\]

\[
= \sup \{ \omega_0 : \mu(\omega_0) = 1 \}.
\]

By these definitions, if the global commons collapses at every initial stock, then the tipping point is infinite.

The tipping point can be distinguished from a carbon threshold above which exists a *safe operating space for humanity*, in the sense of Rockstrom et. al. (2009). In the present model, the global commons under BAU is in a *safe operating space* at \( \omega_0 \) if

\[
\lim_{t \to \infty} \omega^{*t}(\omega_0, \theta^{t-1}) > \omega^{\text{tip}} \quad \text{a.e. } \theta^\infty
\]

This leads naturally to a notion of a *safe operating bound*, defined as a carbon stock \( \omega^{\text{safe}} \) satisfying

\[
\omega^{\text{safe}} = \inf \{ \omega_0 : \text{the commons under BAU is in a safe operating space at } \omega_0 \}.
\]

\[
= \inf \{ \omega_0 : \mu(\omega_0) = 0 \}.
\]

**Proposition 2** Suppose that \( \omega_0 > 0 \). Then \( \mu(\omega_0) \) is weakly decreasing in \( \omega_0 \) and is strictly decreasing on any interval \( (\omega', \omega'') \) for which \( \mu(\omega_0) \in (0, 1) \) \( \forall \omega_0 \in (\omega', \omega'') \).
The proof is in the Appendix. By the Proposition, it follows that $\omega_{\text{safe}} \geq \omega_{\text{tip}}$ with strict inequality if $\omega_{\text{safe}}$ is finite and $\pi$ is non-degenerate. In particular, if there is no variation in $\theta_t$, i.e., if $\theta_t$ is constant over all $t$, then $\omega_{\text{safe}} = \omega_{\text{tip}}$. If the interval $(\omega_{\text{tip}}, \omega_{\text{safe}})$ is nonempty, then it consists of stocks that are neither safe nor collapsing. In this interval tipping is stochastically determined by the evolution of factor elasticities. The various regions are delineated below.

Consider, as an example a stationary Markov process on the two profiles $\{\theta', \theta''\}$ with $\theta' < \theta''$. Suppose that either profile can be reached from the other each period with positive probability bounded away from 0. There are two possibilities. Either the carbon dynamic has a finite tipping point or it does not. The case of a finite tipping point is displayed in Figure 3. Since the equilibrium carbon dynamic for both stocks has fixed points, the tipping point $\omega_{\text{tip}}$ corresponds to the lowest unstable fix point. From any stock strictly larger than $\omega_{\text{tip}}$, the process can avoid collapse with positive probability. In particular, if it reaches stock $\omega_{\text{safe}}$, then the commons is guaranteed to avoid collapse, thus defining the safe operating space (SOS) described in the planetary boundaries literature of Rockstrom et. al (2009), Anderies et. al. (2013), and others.

The case where the tipping “point” is infinite is displayed in Figure 4. In this case the parameters generate certain collapse. Specifically, from any stock $\omega$ and any initial profile, for any time length $T$, there is a date $t$ at which the process will remain “stuck” at $\theta''$ for $T$ periods starting from $t$. Since this occurs at infinitely many $t$, then for $T$ sufficiently long the commons will eventually collapse from $\omega$ with probability one. Consequently, $\omega_{\text{tip}} = \infty$.

Finally, when $b = 0$ then $\mu(\omega_0) = 0$ for any $\omega_0 > 0$. In other words, $\omega_{\text{tip}} = 0$ and so tipping never occurs. In this case, the BAU equilibrium law of motion $\omega_{t+1}(\omega_t, \theta_t)$, derived from (8), converges to a stationary distribution on the carbon stock (a stable carbon cycle) if the underlying process on $\theta^\infty$ is ergodic. This is illustrated in a particularly simple case. Consider a two-state stationary, irreducible Markov process on the two bounds $\underline{\theta}$ and $\overline{\theta}$ with $p$ denoting the switching probability between the two. Figure 5 displays a literal cycle when $p = 1$, that is, when the process alternates deterministically between $\underline{\theta}$ and $\overline{\theta}$. The equilibrium dynamic then cycles between carbon stocks, $\omega^a$ and $\omega^b$.

For this to hold $F$ cannot be too large. See Footnote 7 for an upper bound on $F$.14
Figure 3: Carbon dynamics with tipping point is $\omega^{tip}$

Figure 4: Carbon dynamic with certain collapse.
3.3 Equilibrium Incentives with Tipping Points

Two polar cases illustrate how the equilibrium incentives are affected by tipping. Suppose first that the initial stock $\omega_0$ is sufficiently large so $\mu(\omega_0) = 0$, i.e., the economy remains in the safe operating space. Formally, this means $1_{\omega_t, E_t} = 1$ with probability one in all periods $t$. The carbon dynamic then reduces to $\omega_{t+1} = A(\omega_t - C_t - b)^\gamma$. An increase in the bound $b$ therefore increases the marginal cost of extraction, and so $e^*_i(\omega_t, \theta_t) < \bar{e}_i(\theta_t)$. That is, the BAU equilibrium extraction rate in the tipping model ($\ b > 0$) is less than that in the non-tipping model.

Next, suppose that $\omega_0$ is small enough so that $\mu(\omega_0) = 1$, i.e., collapse is certain. This occurs, for instance, if $A(\omega_t(1 - E_t^*) - b)^\gamma \leq F$ so that $1_{\omega_t, E_t} = 0$ in the current period $t$. But this means $\frac{\partial \omega_{t+1}}{\partial e_{it}} = 0$, in other words, the country’s marginal cost of extraction is zero. Since current extraction rates do not affect future stocks, each country therefore solves a one period static problem. Each country solves its static first order condition

$$\frac{\theta_{it}}{e_{it}} = \frac{1 - \theta_{it}}{1 - E_t} = 0.$$

corresponding to the case where the marginal extraction cost is zero. Country $i$’s BAU equilibrium extraction then coincides with its one-shot or static equilibrium extraction rate is $e^{\text{static}}_i(\theta_t) = \frac{\theta_{it}}{1 - \theta_{it}} \left(1 + \sum_j \frac{\theta_{jt}}{1 - \theta_{jt}}\right)^{-1}$. In the static equilibrium, countries extract...
carbon as if $\delta = 0$.

It follows that $e^*_i(\omega_t, \theta_t) > \bar{e}_i(\theta_t)$. Hence, if the constraint $1^*_{\{\omega_t, \xi_t\}} = 0$ holds or will hold with high probability in the near future, countries have little to lose by extracting as much as possible for the present. Notice that $e^{static}_i(\theta_t) > \bar{e}_i(\theta_t)$ where the latter is the closed form calculated in the no-tipping special case.

Taken together, the two polar cases can be summarized as follows: the off-take parameter $b$ reduces the incentives to extract carbon when the threat of tipping is low, but increases the incentive to extract when the tipping threat is large. This intuition is expressed formally below.

**Theorem 1** If $b > 0$, then for each country $i$, there exists $\omega^1$ and $\omega^2$ with $\omega^1 \leq \omega^2$ such that

1. if $\omega_t \geq \omega^2$ then $e^*_i(\omega_t, \theta_t) < \bar{e}_i(\theta_t)$ and $e^*_i(\omega_t, \theta_t)$ is non-decreasing in $\omega_t$, and
2. if $\omega_t \leq \omega^1$ then $e^*_i(\omega_t, \theta_t) = e^{static}_i(\theta_t) > \bar{e}_i(\theta_t)$.

Part 1 asserts that countries exhibit greater caution when there is tipping threat if $\omega_t$ is large, i.e., when the threat of tipping is relatively low. Part 2 asserts that countries’ extraction rates are higher when there is a tipping threat if $\omega_t$ is low, i.e., when the threat of tipping is relatively high. Of course, the likelihood of reaching
the threshold is endogenous. Later on, we show that there are realized values of the elasticity path profile in which the threshold will be reached, and that this incentives accelerate one’s extraction rate intensify with the level of strategic competition.

The proof is in the Appendix. Figure 6 demonstrate the non-monotonicity of a country’s equilibrium extraction as the current stock varies. For low enough stock, the extraction resembles a static solution $e^{\text{static}}$ where current extraction has no effect on future payoffs. For large enough stock, the extraction resembles the BAU equilibrium in the no-tipping model ($b = 0$). Because the equilibrium extraction rates approach each constant rate from below, the lowest extraction rate in equilibrium occurs for intermediate stocks, as shown in the Figure.

The Figure indicates that proximity to tipping leads countries to accelerate their rate of extraction. The result is reminiscent of the “Green Paradox” (Sinn (2008)), whereby the extraction increases when more stringent emissions regulations are anticipated in the future. In that case, acceleration can mitigated by a more gradual policy implementation. Sakamoto (2014) obtains a related result in a model where an exogenous tipping point determines a stochastic shift from a good environmental state to a bad one.

In our case, both the tipping point and the acceleration are jointly derived in equilibrium. Of particular interest is in how different countries react to the anticipated acceleration. Figures 7 and 8 illustrates the difference between two countries in three possible carbon stocks $\omega_L < \omega_M < \omega_H$. Figure 7 illustrates the trade offs for a low elasticity country. Extraction is relatively undesirable, and this makes tipping unlikely. The equilibrium extraction rate is therefore increasing $\omega_t$. Figure 8 displays a high elasticity country. Extraction is highly desirable making tipping more likely. The extraction rate is therefore increasing as the stock decreases.

The Figures illustrate how the proximity to tipping leads larger $\theta_{ht}$ types to accelerate their extraction rates faster than lower $\theta_{ht}$ types. There is increased the dispersion in extraction rates across high elasticity and low elasticity countries as tipping approaches.

### 3.4 Reaching a Tipping Point

With tipping there are parameter configurations under which an economy will collapse, and alternative configurations under which the commons remains in the safe operating space.

**Theorem 2** Suppose that $[\underline{\theta}, \overline{\theta}] = [0, 1]$. 
Figure 7: BAU extraction rates with Low $\theta_{it}$
Figure 8: BAU extraction rates with High $\theta_{it}$
1. Let \( \pi \) satisfy: for any integer \( T \), any \( \epsilon > 0 \), and a.e. \( \theta^{\infty} \),
\[
\int_{\theta_{t+s} \in (1-\epsilon,1]} \pi(\theta_{t+s}|\theta_{t+s-1}) d\theta_{t+s} \geq \epsilon
\]
for all \( s = 1, \ldots, T \) and infinitely many \( t \). Then there exists \( n' \) such that \( n \geq n' \) implies that the global commons under BAU collapses at every \( \omega_0 \) (i.e., \( \omega^{tip} = \omega^{safe} = \infty \)).

2. There exists \( \epsilon > 0 \) such that if, for almost every \( \theta^{\infty} \),
\[
\theta_t \in [0, \epsilon]^n \quad \forall \ t
\]
then the global commons has a finite tipping point \( \omega^{tip} \).

Part 1 asserts that if there are sufficiently many countries and if for almost every process the carbon elasticities will become and remain high for \( T \) periods for any \( T \), the commons will collapse in the BAU equilibrium. The result can be generated by many types of stochastic processes on \( \theta \) consistent with the historical pattern of increased reliance on fossil fuels.

Part 2 asserts that finite tipping points exist if for almost every process the carbon elasticities remain low. In that case, collapse is avoided if the stock starts out large enough. The proof is in the Appendix. Notice that the sufficient conditions for Part 1 are, in a sense, less restrictive than those of Part 2. To guarantee at least the possibility of reaching a safe operating space, the process cannot stay very long at any point in time in profiles with high elasticities of extraction.

In comparing the assumptions underlying Parts 1 and 2, notice that far less is required to guarantee a collapse. The process needs to hit the high range of elasticities at some point in time, and remain there for a while. This will be generally true of ergodic processes with full support. It also holds for a wide class of super martingales.

The Theorem makes clear that while the proximate cause of tipping is the depletion of the carbon stocks, the “deeper” parameters that drive the tipping and collapse are technological: the factor elasticities that determine the mix of extracted and stored carbon.

The Theorem’s logic is straightforward. Let \( E^*(\omega_t, \theta_t, b, n) \) denote the BAU equilibrium aggregate extraction rate, expressed as a function of the relevant parameters. First, as \( \theta_t \to 0 \equiv (0, \ldots, 0) \), it happens that \( E^*(\omega_t, \theta_t, b, n) \to 0 \). This is intuitive since in the limit elasticities are uniformly zero and so countries do not care at all about individual carbon extraction. In that case, the equilibrium law of motion equals the law of motion without human consumption — the latter always has a finite tipping point which will not be approached if the initial stock is large enough.
By contrast, observe that it is not true that $E^*(\omega_t, \theta_t, b, n) \to 1$ as $\theta_t \to 1 \equiv (1, \ldots, 1)$. That is, even when the ecosystem is not valued at all, countries will not fully extract the stock in equilibrium. This simply because their desire smooth inter-temporal consumption leads to some degree of temporal rationing. This was, in fact, first observed by Levhari and Mirman who analyzed precisely the case $\theta_t = 1$ (without the bound $b$). Nevertheless, it is easy to show that $E^*(\omega_t, \theta_t, b, n) \to 1$ as both $\theta_t \to 1$ and $n \to \infty$. In other words, full extraction does occur in any commons problem when the number of participants is large enough. Thus, when the stochastic process on elasticities moves the global economy to this limiting case for a large enough period of time, a global collapse occurs.

One limitation of Theorem 1 is that it only deals with tail events, i.e., tipping properties are only stated for elasticities close to 1 or close to 0. Whether the tail events occur depends on the likelihood of collapse. Part 1, for instance, can be shown to hold if the Markov process is stationary, ergodic, and has full support. Generally, tipping is more likely in distributions that place increasing weight on higher elasticity profiles.

To see this, start with the original Markov kernel $\pi$, then let $\tilde{\pi}$ be another Markov kernel associated with probability $\tilde{P}$ on the same measurable space $(\Theta^\infty, \mathcal{F})$. The density $\pi$ will be said to dominate $\tilde{\pi}$ (we write $\pi \succ_D \tilde{\pi}$) if for all $t$ and all $\theta_t$ and all nondecreasing functions $w(\theta)$,

$$
\int_{\theta_{t+1}=\theta} \cdots \int_{\theta_{n+1}=\theta} w(\theta_{t+1}) \pi(\theta_{t+1}|\theta_t) d\theta_{t+1} \geq \int_{\theta_{t+1}=\theta} \cdots \int_{\theta_{n+1}=\theta} w(\theta_{t+1}) \tilde{\pi}(\theta_{t+1}|\theta_t) d\theta_{t+1}
$$

The definition above is a standard one for multivariate stochastic dominance, although there are others. We use it to show that the likelihood of collapse is stochastically increasing in carbon usage elasticities.

**Theorem 3** Suppose that $\omega_0 > F$ and $\pi \succ_D \tilde{\pi}$. Then $\mu(\omega_0) \geq \tilde{\mu}(\omega_0)$ and $\omega_{\text{tip}} \geq \tilde{\omega}_{\text{tip}}$, and these inequalities are strict if $\tilde{\omega}_{\text{tip}} < \infty$.

### 4 Optimal Extraction and Optimal Tipping Points

The BAU equilibrium can also be compared to the socially efficient rate carbon usage. The latter is defined as the solution to a utilitarian social planner’s problem. From this planner’s perspective, an Markov-contingent plan, denoted by $c^*(\omega_t, \theta_t) =$

---

15See Zoli (2009) or Maasoumi and Yalonetzky (2013).
(c^\circ_1(\omega_t, \theta_t), \ldots, c^\circ_n(\omega_t, \theta_t)), is optimal if it solves
\[
\max_{\mathbf{c}^\circ} \mathbb{E} \left[ \sum_{i=1}^n \sum_{t=0}^\infty \delta^t u(y_{it}) \bigg| \omega_0, \theta_0 \right] \quad \text{subject to (1) and (3).} \quad (11)
\]

As with the BAU equilibrium, combining log utility with the production technology (1) in the planner’s objective, an optimal plan \( \mathbf{c}^\circ \) solves the Bellman’s equation
\[
V(\omega_t, \mathbf{c}^\circ, \theta_t) = \\
\max_{\mathbf{c}^\circ} \left\{ \sum_{i=1}^n \theta_{it} \log c_{it} + (1 - \theta_{it}) \log(\omega_t - C_t) + \delta \, E \left[ V(\omega_{t+1}, \mathbf{c}^\circ, \theta_{t+1}) \bigg| \omega_t, \theta_t \right] \right\} \\
(12)
\]

One can interpret the planner’s problem as an “ideal benchmark” against which BAU equilibrium may be compared. Alternatively, the planner’s problem can be viewed as the result of an international agreement. The planner’s solution can then be interpreted as the prescribed carbon usage in an alternative Subgame Perfect equilibrium — albeit one that requires agreed-upon triggers to punish deviations.  

4.1 Equilibrium Over-extraction

The forward solution to the planner’s Euler equation yields:
\[
\frac{\theta_{it}}{e^\circ_i(\omega_t, \theta_t)} - \sum_{j=1}^n (1 - \theta_{jt}) \frac{1}{1 - e^\circ_j(\omega_t, \theta_t)} = nG^\circ(\omega_t, \theta_t) \\
(13)
\]

bau for each country \( i \), where \( G^\circ \) has the same functional form as a country’s equilibrium marginal extraction cost (MEC) in (7), except that \( G^\circ \) is evaluated at the socially optimal profile \( e^\circ \). Because the planner internalizes the effect of country \( i \)’s extraction on the global economy, the social MEC is \( nG^\circ \). The left-hand side then determines the social marginal benefit from increasing \( i \)’s carbon extraction.

**Theorem 4** Let \( \mathbf{c} \) be a BAU equilibrium and \( \mathbf{c}^\circ \) an optimal plan. Then for any state \( (\omega_t, \theta_t) \), \( C^*(\omega_t, \theta_t) > C^\circ(\omega_t, \theta_t) \), i.e., the BAU equilibrium is characterized by aggregate over-extraction.

---

\(^{16}\) The construction of such triggers is non-trivial in this heterogeneous environment. Barrett (2013) explores the problems with international coordination when the location of a tipping threshold is uncertain. In a prior paper (Harrison and Lagunoff (2014)), we show that the planner’s solution cannot necessarily be implemented by simple reversion to Markov Perfect (BAU) equilibrium in the event of a deviation.
By itself, the Proposition is not surprising. It serves mainly as a useful background check, verifying that the tipping threshold $b$ does not eliminate the free rider problem in the aggregate. The Proposition also implies that the BAU equilibrium transition $\omega^*_{t+1}(\omega_t, \theta_t)$ on the carbon stock is lower than its efficient counterpart $\omega^0_{t+1}(\omega_t, \theta_t)$ for every realized state $(\omega_t, \theta_t)$.

Unlike many common pool problems, it is not generally true here that all individual countries over-extract. The next section considers the benchmark model without the tipping threshold (i.e., the case where $b = 0$). In this special case, some countries will under-extract relative to the planner’s optimum.

**Social optimum in the No-tipping Model.** When $b = 0$, the planner’s optimal extraction plan has, in fact, a closed form solution

$$ c^o_i(\omega_t, \theta_{it}) = \frac{\phi_{it}}{n} \omega_t \quad \forall \ i $$

where, recall, $\phi_{it} \equiv \theta_{it}(1 - \gamma \delta)$. Not surprisingly, each country’s carbon emission is increasing in its resource elasticity, and decreasing in the effective discount factor $\delta \gamma$. The aggregate under-extraction result of Proposition 4 obviously applies to the special case of $b = 0$. However, more can be said here about the comparison between BAU equilibrium and the socially optimal plan.

**Proposition 3** Let $b = 0$ (the no tipping model), and let $c^*$ and $c^o$ represent a BAU equilibrium and the socially optimal plan, resp. Then for any state $(\omega_t, \theta_t)$,

1. For each country $i$, and each profile $\theta_{-i}$ of others’ elasticities, there exists a cutoff carbon elasticity $\tilde{\theta}_i \in [\theta, \bar{\theta}]$ such that for any stock $\omega_t$, and in any date $t$,

   $$ c^*_i(\omega_t, \theta_{it}, \theta_{-i}) \geq (> ) c^o_i(\omega_t, \theta_{it}) \quad \text{if} \quad \theta_{it} \geq (> ) \tilde{\theta}_i, \quad \text{and} $$

   $$ c^*_i(\omega_t, \theta_{it}, \theta_{-i}) \leq (< ) c^o_i(\omega_t, \theta_{it}) \quad \text{if} \quad \theta_{it} \leq (< ) \tilde{\theta}_i, \quad \text{and} $$

2. along any path of realized carbon elasticity profiles $\theta^t$, the relative differences between efficient and equilibrium output $\frac{y^o_t(\omega_0, \theta^t)}{y^*_t(\omega_0, \theta^t)}$, carbon consumption $\frac{c^o_t(\omega_0, \theta^t)}{c^*_t(\omega_0, \theta^t)}$, and carbon stock $\frac{\omega^0_t(\omega_0, \theta^t)}{\omega^*_t(\omega_0, \theta^t)}$ all increase in $t$.

The proof is in the Appendix. Notice that the planner exercise more caution not because of concern that the carbon stock will be fully depleted. Even without any such threat, the planner internalizes the effects of depreciation of the ecosystem on aggregate output.
Significantly, the Proposition demonstrates that while all BAU equilibria are characterized by aggregate over-extraction, individual countries may over- or under-extract depending on their resource elasticity. High intensity carbon users over-extract in the BAU while low intensity users may actually extract less than in the efficient plan. While this is shown only for the special case of a degenerate threshold \((b = 0)\) the strict inequalities suggest that it should hold for small but positive thresholds as well.

The possibility of under-extraction in a Markov equilibrium is unusual but not unheard of. Dutta and Sundaram (1993) show this possibility in a LM resource model where the state variable can trigger a punishment. In our model, smoothness of the Markov strategy rules out Markov “trigger” strategies. Instead, heterogeneity is the key. Under-extraction by low intensity carbon users occurs as a compensating response to massive over-extraction by the high intensity users. Low intensity users never fully compensate, however, since over-extraction always occurs in the aggregate.

4.2 Optimal Tipping Points and International Agreements

It may be possible to avoid imminent collapse by having countries agree to implement the globally optimal emissions plan. At this point, another sort of tipping point becomes relevant: the threshold stock above which an optimal emissions plan can forestall collapse. The main result of this section establishes that as long as the initial carbon stock is not too low, it is always possible to construct an agreement to forestall collapse.

The optimal tipping point, denoted by \(\omega_{\text{otip}}\), is the threshold below which economy collapses under the welfare maximizing planner’s solution:

\[
\omega_{\text{otip}} = \sup\{\omega_0 : \text{the planner’s commons collapses at } \omega_0\}.
\]

Tipping point \(\omega_{\text{otip}}\) a point at which it is too late for the countries to avoid collapse even if they sign on to an international agreement that implements the optimal extraction plan. Not surprisingly, one can verify that \(\omega_{\text{otip}} \leq \omega_{\text{tip}}\). The inequality, moreover, is strict, if the policy tipping point is finite and if \(\theta > 0\). This follows directly from the fact that \(\mathcal{E}^*(\omega, \theta_t; b) > \mathcal{E}^c(\omega, \theta_t; b)\) in any state pair \((\omega_t, \theta_t)\). The policy tipping point thus provides the economy more breathing space to avoid collapse. This is especially important in the case of Part 1 in the Theorem — the parameters under which collapse is certain in the business-as-usual equilibrium. In that case, a coordinated international agreement is necessary.

Below, we prove that policy tipping points are always finite, and so it is always possible to avoid collapse if the initial carbon stock is not too low.
**Theorem 5** In any global commons, the optimal tipping point $\omega_{\text{otip}}$ is finite.

As before, the proof is in the Appendix. The policy tipping point thus leads to a more nuanced delineation of the state space as follows

\[ b \quad \omega_{\text{otip}} \quad \omega_{\text{tip}} \quad \omega \]

Notice, moreover, that for any stock $\omega_t$ with $\omega_{\text{otip}} < \omega_t < \omega_{\text{tip}}$, the international community has a stochastic but finite period of time to implement an optimal international agreement in order to avert a collapse.

## 5 Conclusion

This paper formulates a model of global carbon consumption that integrates strategic incentives of countries into a dynamic model of nonlinear carbon emissions. Our focus is specifically on the strategic interaction among the largest players — the countries themselves. The objective is to understand the strategic incentives to extract carbon in a business-as-usual equilibrium when tipping is possible.

The papers models a world in which a country’s GDP depends on both its carbon usage and on the preservation of the global ecosystem. Each country therefore faces a trade off between, on the one hand, extracting and emitting carbon, and on the other, maintaining a stock of stored or “unextracted” carbon to preserve a healthy ecosystem. Countries naturally differ in how they evaluate this trade off, and even the same country can make different trade offs at different points in time, depending on economic shocks.

The results describe scenarios in which consumption and economic output may collapse and shrink if the carbon stock sustaining the ecosystem falls below some critical threshold — a tipping point. The results delineate between stocks the guarantee a safe operating space for humanity from carbon stocks in which tipping can occur. In turn, stocks in which tipping can occur are delineated from those in which tipping must occur. These distinctions are roughly consistent with certain planetary boundaries as defined by Rockstrom et. al. (2009).
In an unsettling result, we show that if the there are sufficiently many participants in the BAU and if output elasticity of extracted carbon is high enough for a long enough time period, a tipping point will certainly be breached. The silver lining is that even in this case, there remains a small window in which tipping may be averted if the countries can depart from BAU and sign on to an effective international treaty to limit emissions.

Together, the results underscore the idea that while the proximate cause of tipping is the ongoing depletion of the carbon stocks (or, equivalently, accretion of atmospheric carbon), the “deeper” parameters that drive the tipping and collapse are technological. Future research may be directed toward understanding of the sources of change for these technologies.

6 Appendix

Proof of Proposition 1. Starting from the Euler equation,

\[
\frac{\theta_i t}{e_i t} = \frac{(1 - \theta_i t)}{(1 - \xi_i t)} + \delta \left[ \frac{\partial E[U_i(\omega_{t+1}, e_i, \theta_{i+1})]}{\partial \omega_{i+1}} \right] \frac{\partial \omega_{i+1}}{\partial e_i t} \bigg|_{\omega_i, \xi_i} = 0
\]

with \( \frac{\partial \omega_{i+1}}{\partial e_i t} = -\frac{A \gamma \omega_i}{(\omega_i (1 - \xi_i) - b)^{1-\gamma}} \). Then the Euler equation is

\[
\frac{\theta_i t}{e_i t} = \frac{(1 - \theta_i t)}{(1 - \xi_i t)} = A \delta \gamma \frac{\partial E[U_i(\omega_{t+1}, e_i, \theta_{i+1})]}{\partial \omega_{t+1}} \frac{\omega_t}{(\omega_t (1 - \xi_t) - b)^{1-\gamma}} \bigg|_{\omega_i, \xi_i}.
\] (15)

Differentiating the value function \( U_i(\omega_{t+1}, e_i, \theta_{i+1}) \) with respect to \( \omega_{t+1} \)

\[
\frac{\partial E[U_j(\omega_{t+1}, e_i, \theta_{i+1})]}{\partial \omega_{t+1}} \bigg|_{\theta_i t} =
\]

\[
E \left[ \frac{1}{\omega_{t+1}} + A \delta \gamma \frac{\partial E[U_i(\omega_{t+2}, e_i, \theta_{i+2})]}{\partial \omega_{i+2}} \frac{\omega_{t+1}}{(\omega_{t+1} (1 - \xi_{t+1}) - b)^{1-\gamma}} \bigg|_{\omega_i, \xi_i} \right].
\]

Substituting this into the first order condition (15), we obtain
which, after iteration, yields
\[
\frac{\theta_{it} - (1 - \theta_{it})}{e_{it}} = \frac{(1 - \theta_{it})}{(1 - \mathcal{E}_t)}
\]

\[
= A \delta \gamma \left\{ \frac{\partial E[U_i(\omega_{t+1}, e_{t+1})]}{\partial \omega_{t+1}} \Big| \theta_{it}, \frac{\omega_t}{(\omega_t(1 - \mathcal{E}_t) - b)^{1-\gamma}} \right\} \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

\[
= \delta \gamma \left\{ \frac{\partial E[U_i(\omega_{t+1}, e_{t+1})]}{\partial \omega_{t+1}} \Big| \theta_{it}, \frac{\omega_{t+1}(1 - \mathcal{E}_{t+1})}{\omega_{t+1}(1 - \mathcal{E}_{t+1}) - b}\right\} \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

\[
= \delta \gamma \left\{ \frac{\omega_t}{(\omega_t(1 - \mathcal{E}_t) - b)^{1-\gamma}} \right\} \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

Reorganizing terms, we obtain the BAU Euler equation
\[
\frac{\theta_{it} - (1 - \theta_{it})}{e_{it}} = \frac{(1 - \theta_{it})}{(1 - \mathcal{E}_t)}
\]

\[
= \delta \gamma \left\{ \frac{\omega_{t+1}(1 - \mathcal{E}_{t+1})}{(\omega_{t+1}(1 - \mathcal{E}_{t+1}) - b)} \right\} \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

\[
= \delta \gamma \left\{ \frac{\omega_{t+1}(1 - \mathcal{E}_{t+1})}{(\omega_{t+1}(1 - \mathcal{E}_{t+1}) - b)} \right\} \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

\[
1 + E \left[ \left( \frac{\theta_{it+1}(1 - \mathcal{E}_{t+1})}{e_{it+1}} - (1 - \theta_{it+1}) \right) \right] \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

which, after iteration, yields
\[
\frac{\theta_{it} - (1 - \theta_{it})}{e_{it}} = \frac{(1 - \theta_{it})}{(1 - \mathcal{E}_t)}
\]

\[
= \delta \gamma \left\{ \frac{\omega_{t+1}(1 - \mathcal{E}_{t+1})}{(\omega_{t+1}(1 - \mathcal{E}_{t+1}) - b)} \right\} \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

\[
= \delta \gamma \left\{ \frac{\omega_{t+1}(1 - \mathcal{E}_{t+1})}{(\omega_{t+1}(1 - \mathcal{E}_{t+1}) - b)} \right\} \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

\[
1 + E \left[ \left( \frac{\theta_{it+1}(1 - \mathcal{E}_{t+1})}{e_{it+1}} - (1 - \theta_{it+1}) \right) \right] \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

\[
(16)
\]

\[
\frac{\theta_{it} - (1 - \theta_{it})}{e_{it}} = \frac{(1 - \theta_{it})}{(1 - \mathcal{E}_t)}
\]

\[
= \delta \gamma \left\{ \frac{\omega_{t+1}(1 - \mathcal{E}_{t+1})}{(\omega_{t+1}(1 - \mathcal{E}_{t+1}) - b)} \right\} \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

\[
= \delta \gamma \left\{ \frac{\omega_{t+1}(1 - \mathcal{E}_{t+1})}{(\omega_{t+1}(1 - \mathcal{E}_{t+1}) - b)} \right\} \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

\[
1 + E \left[ \left( \frac{\theta_{it+1}(1 - \mathcal{E}_{t+1})}{e_{it+1}} - (1 - \theta_{it+1}) \right) \right] \mathcal{1}_{\{\omega_t, \mathcal{E}_t\}}
\]

\[
(17)
\]

30
Multiplying both sides by $1 - E_t$ yields Equation (7).

Finally, by setting $b = 0$ as required for the no-tipping model, we obtain the closed solution for a BAU equilibrium in Equation (8).

**Proof of Proposition 2.** Let $\omega_0 > \bar{\omega}_0 > F$. It suffices to show

$$P\left(\left\{\theta^\infty: \lim_{t \to \infty} \omega_t^*(\omega_0, \theta^t) \leq \omega_{\text{tip}}\right\}\right) < P\left(\left\{\theta^\infty: \lim_{t \to \infty} \omega_t^*(\bar{\omega}_0, \theta^t) \leq \omega_{\text{tip}}\right\}\right).$$

In turn, this holds if

$$\omega_t^*(\omega_0, \theta^t) > \omega_t^*(\bar{\omega}_0, \theta^t) \quad \forall \theta^t \forall t.$$

We proceed by induction. Observe that

$$\omega_t^*(\omega_0, \theta^t) = A(\omega_t^* - C^* - j(\omega_0, \theta^t))^{\gamma}$$

and so we proceed by induction. Suppose, by contradiction, that for $t = 1$,

$$\omega_1^*(\omega_0, \theta_0) = A(\omega_0 - C^*(\omega_0, \theta_0))^{\gamma} < A(\bar{\omega}_0 - C^*(\bar{\omega}_0, \theta_0))^{\gamma} = \omega_1^*(\bar{\omega}_0, \theta_0).$$

In particular, this implies

$$\omega_0 - C^*(\omega_0, \theta_0) < \bar{\omega}_0 - C^*(\bar{\omega}_0, \theta_0).$$

Notice, first, that it is not possible for $\omega_0 - C^*_i(\omega_0, \theta_0) < \bar{\omega}_0 - C^*_i(\bar{\omega}_0, \theta_0)$ for all $i$. If that were true, then $c^*_i(\omega_0, \theta_0) < c^*_i(\bar{\omega}_0, \theta_0)$ for all $i$, a contradiction of the fact that $C^*(\omega_0, \theta_0) > C^*(\bar{\omega}_0, \theta_0)$ when $c^*_i$ is increasing in $\omega_0 - C^*(\omega_0, \theta_0)$ and given $\omega > \bar{\omega}$.

Hence, there is some country $j$ for whom

$$\omega_0 - C^*_j(\omega_0, \theta_0) > \bar{\omega}_0 - C^*_j(\bar{\omega}_0, \theta_0) \quad \text{and} \quad c^*_j(\omega_0, \theta_0) > c^*_j(\bar{\omega}_0, \theta_0).$$

For this country $j$, payoffs in an arbitrary state $\omega_0$ and for an arbitrary choice $c_j$ can be expressed as

$$\theta_{it} \log c_j + (1 - \theta_{it}) \log(\omega_0 - C^*_j(\omega_0, \theta_0) - c_j) + \delta E[V(\omega_0 - C^*_j(\omega_0, \theta_0) - c_j)].$$

By strict concavity of this objective as a function of $c_j$, $c^*_j(\omega_0, \theta_0)$ is optimal in state $\omega_0$ only if

$$c^*_j(\omega_0, \theta_0) - c^*_j(\bar{\omega}_0, \theta_0) \leq (\omega_0 - C^*_j(\omega_0, \theta_0)) - (\bar{\omega}_0 - C^*_j(\bar{\omega}_0, \theta_0)).$$
Proceeding by induction, it can be established that for all \( t \),
\[ \omega^*(t, \theta^t) > \omega^*(\bar{t}, \theta^t) \quad \forall \theta^t \quad \forall t. \]

We thus conclude the proof.

**Proof of Theorem 1.** Returning to the fundamental Euler equation (6), notice that if we let
\[ Z_{it} = \frac{\theta_{it}(1 - E^t_{it})}{1 - (\theta_{it})} \]
and
\[ \Gamma(\omega_t, \theta_t) = \left( \frac{\delta \gamma \omega_t(1 - E^*(\omega_t, \theta_t))}{\omega_t(1 - E*(\omega_t, \theta_t)) - b} \right) 1_{\{\omega_t, E^*(\omega_t, \theta_t)\}} \]
Then the Euler equation (6) can be expressed as
\[ Z_{it} = \Gamma(\omega_t, \theta_t) \left( 1 + E \left[ Z_{it+1} \left| \omega_t, \theta_{it} \right. \right] \right) \quad (18) \]

In the case of \( b = 0 \), we have
\[ Z^0_{it} = \delta \gamma \left( 1 + E \left[ Z^0_{it+1} \left| \omega_t, \theta_{it} \right. \right] \right) \quad (19) \]

Observe that \( \Gamma(\omega_t, \theta_t) > \delta \gamma \) whenever \( 1_{\{\omega_t, E^*(\omega_t, \theta_t)\}} = 1 \) and \( \Gamma(\omega_t, \theta_t) = 0 \) otherwise. Ignoring the notational dependence on \( \theta_t \) for now, let
\[ z_i(\omega_t, X) = \Gamma(\omega_t, \theta_t) (1 + X) \quad (20) \]
and
\[ z^0_i(X) = \delta \gamma (1 + X) \quad (21) \]

In other words, \( z_i(\omega_t, X) \) and \( z^0_i(X) \) express their dependences on the expected future value of \( Z_{it+1} \) as an arbitrary right-hand side variable \( X \) in (18) and (19), respectively. Clearly both \( z_i \) and \( z^0_i \) are increasing in \( X \). Since \( e_{it} \) is bounded away from 0 and 1, it follows that \( X \) is bounded as well.

Then there exists \( \omega^1 \) and \( \omega^2 \) with \( \omega^1 \leq \omega^2 \) such that for all \( X \),
\[ z_i(\omega_t, X) > z^0_i(X) \quad if \quad \omega_t \geq \omega^2, \quad and \]
\[ z_i(\omega_t, X) < z^0_i(X) \quad if \quad \omega_t \leq \omega^1 \]
By backward induction from any fixed $X$, 

$$Z_{it} > Z^0_{it} \text{ if } \omega_t \geq \omega^2, \text{ and}$$

$$Z_{it} < Z^0_{it} \text{ if } \omega_t \leq \omega^1,$$

for each $t$. By the definition of $Z$ and $Z^0$, we obtain

$$e^*_i(\omega_t, \theta_t) < \bar{e}_i(\theta_t) \text{ if } \omega_t \geq \omega^2, \text{ and}$$

$$e^*_i(\omega_t, \theta_t) > \bar{e}_i(\theta_t) \text{ if } \omega_t \leq \omega^1$$

Next, observe that if $\omega_t \geq \omega^2$ then $e^*_i(\omega_t, \theta_t)$ is weakly increasing at $\omega_t$ if $\Gamma(\omega_t, \theta_t)$ is weakly decreasing at $\omega_t$. Observe that if $\Gamma(\omega_t, \theta_t)$ is decreasing then $\omega_t(1 - \mathcal{E}^*(\omega_t, \theta_t))$ is increasing, which is only possible if $\mathcal{E}^*(\omega_t, \theta_t)$ is increasing, a contradiction. We conclude that $e^*_i(\omega_t, \theta_t)$ is weakly increasing if $\omega_t \geq \omega^2$.

If $\omega_t \leq \omega^1$, then $\Gamma(\omega_t, \theta_t) = 0$ in which case $e^*_i(\omega_t, \theta_t) = e^{\text{static}}_i(\theta_t)$. We conclude the proof.

**Proof of Theorem 2.** Let $\mathcal{E}^*(\omega_t, \theta_t, b, n)$ denote the equilibrium aggregate extraction rate, expressed as a function of the relevant parameters.

**Part 1.** We first show that there is a stationary lower bound independent of $\omega_t$, namely, $\mathcal{E}(\theta_t, b, n) \leq \mathcal{E}^*(\omega_t, \theta_t, b, n) \forall \omega, t$ with the property that for $\theta_t \in (1 - \epsilon, 1]^n$ and $\epsilon$ small enough and $n$ large enough, we have

$$\omega_t > \omega^*_{t+1}(\omega_t, \theta_t; b) \forall \omega_t.$$

To find a stationary lower bound, observe that $1_{(\omega_t, \xi_t)} = 0$ for all $\omega_t$ such that $A(\omega_t(1 - \mathcal{E}_t) - b)^\gamma \leq F$ or equivalently, $\omega_t \leq \frac{1}{1 - \xi_t} \left( b + (\frac{F}{A})^{1/\gamma} \right) \equiv K$. Moreover, $K$ is the upper bound on stocks for which $1_{(\omega_t, \xi_t)} = 0$. Hence, the marginal future cost of extraction, $G^*(\omega_t, \theta_t, b)$ is bounded above by its stationary limit when $\omega$ approaches $K$ from the right, so that $1_{(\omega_t, \xi_t)} = 1$. Stated precisely:

$$\forall \omega_t \leq K, \quad G^*(\omega_t, \theta_t, b) \leq \lim_{\omega \searrow K} G^*(\omega, \theta_t, b).$$
The Euler equation (6) in this limit is

\[ \frac{\theta_{it}(1 - \mathcal{E}_t)}{e_{it}} - (1 - \theta_{it}) = \delta \gamma \frac{K(1 - \mathcal{E}_t)}{K(1 - \mathcal{E}_t) - b} \left( 1 + \frac{\theta_{it}(1 - \mathcal{E}_t)}{e_{it}} - (1 - \theta_{it}) \right). \] (22)

By construction, (22) is the limiting Euler equation to which \( E(\theta_t, b, n) \) is a solution.

Taking \( \theta_t \to 1 \), it follows that \( e_i = \mathcal{E}/n \) and the Euler equation becomes

\[ \frac{n(1 - \mathcal{E})}{\mathcal{E}} = \delta \gamma \frac{K(1 - \mathcal{E})}{K(1 - \mathcal{E}) - b} \left( 1 + \frac{n(1 - \mathcal{E})}{\mathcal{E}} \right) \]

which can be expressed as

\[ \frac{n - \mathcal{E}}{\mathcal{E}} = \frac{\delta \gamma K(1 - \mathcal{E})}{(1 - \delta \gamma)K(1 - \mathcal{E}) - b}. \]

Using the fact that \( K \equiv \frac{1}{1 - \mathcal{E}} \left( b + \left( \frac{\mathcal{E}}{A} \right)^{1/\gamma} \right) \), the Euler equation becomes

\[ \frac{n - \mathcal{E}}{\mathcal{E}} = \frac{\delta \gamma \left( b + \left( \frac{\mathcal{E}}{A} \right)^{1/\gamma} \right)}{(1 - \delta \gamma) \left( b + \left( \frac{\mathcal{E}}{A} \right)^{1/\gamma} \right) - b}. \] (23)

Since, by construction \( \mathcal{E}(1, b, n) \) satisfies (23), it is easy to see that

\[ \lim_{n \to \infty} \mathcal{E}(1, b, n) = 1. \]

Next we show that for \( \epsilon \) small enough and \( n \) large enough,

\[ \omega_t > \omega_{t+1}^*(\omega_t, \theta_t; b) \quad \forall \omega_t \quad \forall \theta_t \in (1 - \epsilon, 1)^n. \] (24)

The inequality (24) may be rewritten as

\[ \left( \frac{1}{(1 - \mathcal{E}^*(\omega_t, \theta_t; b, n))} \left[ \frac{\omega_t}{A} \right]^{1/\gamma} + b \right) - \omega_t > 0 \quad \forall \omega_t. \] (25)

To verify that (25) holds, we show that

\[ P = \min_{\omega} \left( \frac{1}{(1 - \mathcal{E}(\omega_t; b, n))} \left[ \frac{\omega}{A} \right]^{1/\gamma} + b \right) - \omega > 0 \]

where \( \mathcal{E}_t(\omega_t; b, n) \) is, recall, a stationary lower bound of \( \mathcal{E}^*(\omega_t, \theta_t; b, n) \).

The first order condition for \( P \) is

\[ (\gamma(1 - \mathcal{E}(\theta_t; b, n))A^{1/\gamma})^{-1} \omega^{1/\gamma} - 1 = 0. \]
Solving for $\omega$, we obtain $\omega^m \equiv (\gamma(1 - \mathcal{E}(\theta; b, n)))^{1/\gamma} A^{1/\gamma}$. Substituting $\omega^m$ back into the problem we obtain,

$$
P = \left( \frac{1}{(1 - \mathcal{E}(\theta; b, n))} \left[ \frac{(\omega^m)^{1/\gamma} + b}{A} - \omega^m \right] \right) = \frac{b}{1 - \mathcal{E}(\theta; b, n)} = \left( (1 - \mathcal{E}(\theta; b, n))^{1/\gamma} A^{1/\gamma} \right) \left( \gamma^{1/\gamma} - \gamma^{1/\gamma} \right).
$$

Hence, (25) holds if

$$
P = \frac{b}{1 - \mathcal{E}(\theta; b, n)} = \left( (1 - \mathcal{E}(\theta; b, n))^{1/\gamma} A^{1/\gamma} \right) \left( \gamma^{1/\gamma} - \gamma^{1/\gamma} \right) > 0 \quad (27)
$$

holds. But (27) clearly holds in the limit as $\theta_t \to 1 \equiv (1, \ldots, 1)$ and $n \to \infty$ since $\mathcal{E}(\theta_t; b, n) \to 1$ in that case.

Since the argument is strict, it holds for sufficiently large $n$ and $\theta_t$ sufficiently close to one. Thus, for any fixed profile if $\theta_t$, there is a finite time length $T(\theta_t)$ such that $\omega^* (\omega_0, \theta^t) \to F$ in at most $T(\theta_t)$ iterations. Let

$$
T = \max_{\theta_t \in [1-\epsilon,1]} T(\theta_t).
$$

Thus $T$ is a time length (dependent on $\omega_0$) such that if (24) holds for all $\theta_t \in (1-\epsilon, 1]^n$ then $\omega^* (\omega_0, \theta^t) \to F$ in at most $T$ iterations.

Observe that (9) implies for any finite $T > 0$, that for a.e. $\theta_t$,

$$
\Pr \left( \theta_{t+s} \in (1-\epsilon, 1]^n, \ s = 1, \ldots, T \ \bigg| \ \theta_t \right) = \int_{\theta_{t+1} \in (1-\epsilon, 1]^n} \cdots \int_{\theta_{t+T} \in (1-\epsilon, 1]^n} \prod_{s=1}^{T} dF(\theta_{t+s} | \theta_{t+s-1}) \geq \epsilon^T. \quad (28)
$$

It follows that for almost every process $\{\theta_t\}$, there is a date $t$ (infinitely many dates actually) such that (24) holds for realized values $\theta_t, \theta_{t+1}, \ldots, \theta_{t+T}$, in which case $\omega^* (\omega_t, \theta^t+T) = F$. Consequently, the economy collapses at $\omega_t$, concluding the proof of Part 1.
Part 2. The proof here largely reverse engineers some of the logic of part 1. In particular, we now find a stationary upper bound \( \mathcal{E}(\theta_t, b, n) \geq \mathcal{E}^*(\omega_t, \theta_t, b, n) \) \( \forall \omega_t \) with the property that for \( \theta_t \in (0, \epsilon]^n \) and \( \epsilon \) small enough, we have

\[
\omega_t < \omega^*_{t+1}(\omega_t, \theta_t; b) \quad \text{on a nonnull set of stocks } \omega_t.
\]  
(29)

Notice that (29) is just the negation of (25).

The simplest upper bound is the extraction rate when each country its static, one shot optimal rate. Namely, we have as our upper bound,

\[
\mathcal{E}(\theta_t, b, n) = \sum_i \frac{\theta_{it}}{1 - \theta_{it}} \left( 1 + \sum_i \frac{\theta_{it}}{1 - \theta_{it}} \right)^{-1}
\]

Now using an analogous argument to that of the steps from Equations (26) to (27), the Inequality in (29) above holds if

\[
\mathcal{P} \equiv \min_{\omega} \left( \frac{1}{(1 - \mathcal{E}(\theta_t; b, n))} \left[ \left( \frac{\omega}{A} \right)^{1/\gamma} + b \right] - \omega \right) < 0
\]  
(30)

The first order condition for \( \mathcal{P} \) is

\[
(\gamma(1 - \mathcal{E}(\theta_t; b, n))A^{1/\gamma} - \omega^{1/\gamma}) - 1 = 0.
\]

Solving for \( \omega \), we obtain \( \omega^0 \equiv (\gamma(1 - \mathcal{E}(\theta_t; b, n)))^{\frac{1}{1-\gamma}}A^{\frac{1}{1-\gamma}} \). Substituting \( \omega^0 \) back into the problem we obtain,

\[
\mathcal{P} = \frac{b}{1 - \mathcal{E}(\theta_t; b, n)} - (1 - \mathcal{E}(\theta_t; b, n))^{\frac{1}{1-\gamma}}A^{\frac{1}{1-\gamma}} \left( \gamma^{\frac{1}{1-\gamma}} - \gamma^{\frac{1}{1-\gamma}} \right).
\]

Hence, (29) holds if

\[
\mathcal{P} = \frac{b}{1 - \mathcal{E}(\theta_t; b, n)} - (1 - \mathcal{E}(\theta_t; b, n))^{\frac{1}{1-\gamma}}A^{\frac{1}{1-\gamma}} \left( \gamma^{\frac{1}{1-\gamma}} - \gamma^{\frac{1}{1-\gamma}} \right) < 0
\]  
(31)

But (31) is easily observed to hold in the limit as \( \theta_t \to 0 \equiv (0, \ldots, 0) \) since

\[
\mathcal{E}(\theta_t, b, n) \equiv \sum_i \frac{\theta_{it}}{1 - \theta_{it}} \left( 1 + \sum_i \frac{\theta_{it}}{1 - \theta_{it}} \right)^{-1} \to 0 \quad \text{as } \theta_t \to 0
\]

in the limit. Since the inequality is strict, (31) holds for \( \theta_t \in [0, \epsilon]^n \) if \( \epsilon \) is nonzero but sufficiently small. This concludes the proof of Part 2.
Proof of Theorem 3. Let $\theta_t \geq \bar{\theta}_t$. Then by the definition of dominance, it suffices to show
\[
\omega^* t(\omega_0, \theta_t) < \omega^* t(\omega_0, \bar{\theta}_t) \quad \forall \omega_0
\] (32)

We now proceed to verify (32). We first show $C^*(\omega_t, \theta_t) > C^*(\omega_t, \bar{\theta}_t)$, in which case (32) holds by an induction argument.

Using the derivation in Appendix ??, the Euler equation for $c^*_t$ can be expressed as
\[
\frac{\theta_{it}(\omega_0 - C_t)}{c_{it}} - (1 - \theta_{it}) = \\
\delta \gamma \left\{ \frac{\omega_t - C_t}{(\omega_t - C_t - b)} \left[ 1 + E \left[ \left( \frac{\theta_{i+1}(\omega_0 - C_{i+1})}{c_{i+1}} - (1 - \theta_{i+1}) \right) \bigg| \omega_t, \theta_{it} \right] \right] \right\}
\] (33)

From (33), it is clear that $c^*_t$ is increasing in $\theta_{it}$, and since $\theta_{-it}$ enters $c^*_t$ only through its effect on $C^*_{-it}$, it follows from the Envelope Theorem that $C^*_t(\theta_t)$ is increasing in $\theta_t$.

The ordering of tipping points follows from the fact that
\[
P \left( \left\{ \theta^\infty : \lim_{t \to \infty} \omega^* t(\omega_0, \theta^t) \to F \right\} \right) = P \left( \left\{ \theta^\infty : \lim_{t \to \infty} \omega^* t(\omega_0, \theta^t) \leq \omega^{tip} \right\} \right) \quad \forall \omega_0
\]
and from Proposition 5.
\[
P \left( \left\{ \theta^\infty : \lim_{t \to \infty} \omega^* t(\omega_0, \theta^t) \leq \omega^{tip} \right\} \right) < P \left( \left\{ \theta^\infty : \lim_{t \to \infty} \omega^* t(\omega_0, \theta^t) \leq \omega^{tip} \right\} \right)
\]

Proof of Theorem 4. The Euler equation in the BAU equilibrium (in (6)) can be expressed as
\[
\left( \frac{\theta_{it} - (1 - \theta_{it})c_{it}}{1 - E_{it}} \right) (\omega_t(1 - E_t) - b) = \\
A\delta \gamma e_{it} \omega_t \left\{ 1 + E \left[ \left( \frac{\theta_{i+1} - (1 - \theta_{i+1})}{e_{i+1}(1 - E_{i+1})} \right) (1 - E_{i+1}) \bigg| \omega_t, \theta_{it} \right] \right\} 1^*_{\omega_t, E_{it}} = 0
\] (34)
Similarly, the Euler equation for the planner’s problem can be expressed as

\[
\frac{1}{n} \left( \theta_{it} - \frac{e_{it} \sum_j (1 - \theta_{jt})}{1 - \mathcal{E}_t} \right) (\omega_t (1 - \mathcal{E}_t) - b) - \\
A\delta \gamma e_{it} \omega_t \left\{ 1 + E \left( \left( \frac{\theta_{it+1}}{e_{it+1}} - \frac{1 - \theta_{it+1}}{1 - \mathcal{E}_{t+1}} \right) (1 - \mathcal{E}_{t+1}) \right) \omega_t, \theta_{it} \right\} 1^*_{\omega_t, \theta_{it}} = 0
\]

(35)

The left-hand sides of Equations (34) and (35) are the marginal values to country \( i \) and the planner, respectively, from \( i \)'s extraction of carbon. Summing both equations over all countries, we obtain,

\[
H^*_t(\mathcal{E}_t, e_{t+1}) \equiv \left( \sum_i \theta_{it} - \sum_i \frac{(1 - \theta_{it}) e_{it}}{1 - \mathcal{E}_t} \right) (\omega_t (1 - \mathcal{E}_t) - b) - \\
A\delta \gamma \mathcal{E}_t \omega_t \left\{ 1 + E \left( \left( \frac{\theta_{it+1}}{e_{it+1}} - \frac{1 - \theta_{it+1}}{1 - \mathcal{E}_{t+1}} \right) (1 - \mathcal{E}_{t+1}) \right) \omega_t, \theta_{it} \right\} 1^*_{\omega_t, \theta_{it}} = 0
\]

(36)

and

\[
H^0_t(\mathcal{E}_t, e_{t+1}) \equiv \frac{1}{n} \left( \sum_i \theta_{it} - \frac{\mathcal{E}_t \sum_j (1 - \theta_{jt})}{1 - \mathcal{E}_t} \right) (\omega_t (1 - \mathcal{E}_t) - b) - \\
A\delta \gamma \mathcal{E}_t \omega_t \left\{ 1 + E \left( \left( \frac{\theta_{it+1}}{e_{it+1}} - \frac{1 - \theta_{it+1}}{1 - \mathcal{E}_{t+1}} \right) (1 - \mathcal{E}_{t+1}) \right) \omega_t, \theta_{it} \right\} 1^*_{\omega_t, \theta_{it}} = 0
\]

(37)

We now compare the marginal values \( H^*_t(\mathcal{E}_t, e_{t+1}) \) and \( H^0_t(\mathcal{E}_t, e_{t+1}) \) on the following Lemmata.

**Lemma 1** The second terms of \( H^*_t(\mathcal{E}_t, e_{t+1}) \) and \( H^0_t(\mathcal{E}_t, e_{t+1}) \), respectively, are identical.

**Proof of Lemma 1.** Clear by inspection.

**Lemma 2** For any \( \mathcal{E} \) satisfying \( \mathcal{E} < \frac{n}{n+1} \),

\[
\sum_i \theta_{it} - \sum_i \frac{(1 - \theta_{it}) e_{it}}{1 - \mathcal{E}_t} > \frac{1}{n} \left( \sum_i \theta_{it} - \frac{\mathcal{E}_t \sum_j (1 - \theta_{jt})}{1 - \mathcal{E}_t} \right)
\]

38
**Proof of Lemma 2.** For simplicity let $\Theta_t = \sum_i \theta_{it}$. Then we seek to show

$$\Theta_t(1 - E_t) - \Theta_t + \sum_i \theta_{it}e_{it} \gtrsim \frac{1}{n} (\Theta_t(1 - E_t) - nE_t + \Theta_tE_t)$$

or

$$\Theta_t(1 - E_t) + \sum_i \theta_{it}e_{it} \gtrsim \frac{1}{n} (\Theta_t(1 - E_t) + \Theta_tE_t)$$

or

$$\Theta_t - \Theta_tE_t + \sum_i \theta_{it}e_{it} \gtrsim \frac{1}{n} \Theta_tE_t$$

or

$$\Theta_t - \Theta_tE_t + \sum_i \theta_{it}e_{it} \gtrsim 0$$

which clearly holds if $\frac{n}{n+1} > E_t$.

Combining Lemma 1 with Lemma 2, it follows that for all $E_t$ satisfying $E_t < \frac{n}{n+1}$, and all $e_{t+1}$,

$$H_t^*(E_t, e_{t+1}) > H_t^0(E_t, e_{t+1}).$$

Since $E_t^0 < \frac{n}{n+1}$,

$$H_t^*(E_t^0, e_{t+1}) > H_t^0(E_t^0, e_{t+1}) = 0,$$

for all $e_{t+1}$. This yields $E_t^* > E_t^0$. □

**Proof of Proposition 3**

**Part 1. Over- and Under-extraction by Individual Countries.** To evaluate whether a country over or under extracts in the BAU equilibrium, one need only compare $e_{it}^0$ to $e_{it}^*$. Country over (under) extracts if $e_{it}^* > (\prec) e_{it}^0$. We therefore compare:

$$e_{it}^0(\theta_t) = \frac{\theta_{it}(1 - A\gamma\delta)}{n} = \frac{\phi_{it}}{n} \gtrsim e_{it}^*(\theta_t) = \frac{\theta_{it}(1 - A\gamma\delta)}{1 + \left(\sum_{j=1}^n \frac{\theta_{jt}(1 - A\gamma\delta)}{1 - \theta_{jt}(1 - A\gamma\delta)}\right)} = \frac{\phi_{it}}{1 - \phi_{it}}$$

with, recall, $\phi_{it} = \theta_{it}(1 - A\gamma\delta)$. Since $\phi_{it} > 0$, country $i$ over-extracts if

$$\frac{\frac{1}{1 - \phi_{it}}}{1 + \left(\sum_{j=1}^n \frac{\phi_{jt}}{1 - \phi_{jt}}\right)} > \frac{1}{n},$$

39
and solving for $\phi_{it}$, country $i$ will over (under) extract if

$$
\phi_{it} > \begin{cases} 
< & 1 - \frac{n - 1}{\sum_{j \neq i} \frac{\phi_{jt}}{1 - \phi_{jt}}} \tag{38}
\end{cases}
$$

By choosing $\tilde{\theta}$ such that $\tilde{\theta}(1 - A \delta \gamma)$ equals the right hand side of (38), we have found out threshold.

Notice, moreover, that the larger the profile of her opponents the (weakly) smaller is the set of types for which is optimal to her over extract.\footnote{Example: suppose a symmetric profile $\phi_{i} - i$, i.e. $\phi_{j} = \phi_{k} = \phi$ for all $k, j \neq i$.}

**Part 2. Output paths.** The final part must prove that relative output, carbon consumption and carbon stock shrinks in the BAU relative to that of the efficient plan.

We first compute the socially optimal extraction rate and the optimal carbon path when $b = 0$ and setting $\phi_{it} = \theta_{it}(1 - A \delta \gamma)$. The extraction rate is: $e_{it} = \frac{\phi_{it}}{n}$ and the time path of the carbon stock in the planner’s optimum is

$$
\omega^* t(\omega_0, \theta^t) = \omega_0^t A \frac{1 - \gamma t}{1 - \gamma} \prod_{\tau = 1}^{t} \left(1 - \mathcal{E}^t(\theta_{t-\tau}) \right)^{\gamma^\tau}
$$

or

$$
\omega_t^* = \omega_t^0 A \frac{1 - \gamma t}{1 - \gamma} \prod_{\tau = 1}^{t} \left(1 - \frac{\sum_{j \neq i} \phi_{jt}}{n} \right)^{\gamma^\tau}.
$$

\footnote{Example: suppose a symmetric profile $\phi_{i} - i$, i.e. $\phi_{j} = \phi_{k} = \phi$ for all $k, j \neq i$.}

Note that the extreme (highest) profile player $i$ can be facing is a profile of opponents with the highest type, i.e. $\theta_j = \bar{\theta} < 1$ for all $j \neq i$. Then from equation (**) above,

$$
\theta_i > \frac{2\bar{\theta}(1 - \gamma \delta) - 1}{\bar{\theta}(1 - \gamma \delta)^2}
$$

or

$$
\phi_i > \frac{2\bar{\theta} - 1}{\phi}.
$$

So if we require all $\theta_i$ over extract, the condition is:

$$
\bar{\theta} > \frac{2\bar{\theta}(1 - \gamma \delta) - 1}{\bar{\theta}(1 - \gamma \delta)^2}.
$$

This implies the following sufficient condition: if $\delta \gamma \geq \frac{1}{2}$ all types $\theta_i$ over extract.
A country’s output path in the social planner’s problem is given by

\[ y^*_t = \left( \frac{\phi_{it}}{n} \right)^{\theta_{it}} \left( 1 - \frac{\sum_j \phi_{jt}^*}{n} \right)^{(1-\theta_{it})} \omega_0^{\gamma^t} A^{1-\gamma^t} \prod_{\tau=1}^t \left( 1 - \frac{\sum_j \phi_{jt-t-\tau}}{n} \right)^\gamma. \] (40)

A particularly useful illustration of (39) is the case without shocks. In that case \( \theta_t = \theta_t' = \theta \) and so (39) reduces to

\[ \omega^*_t(\omega_0, \theta^t) = \omega_0^{\gamma^t} \left( 1 - \frac{\sum_j \phi_j}{n} \right) A^{1-\gamma^t} \] (41)

in which case the output path simplifies to

\[ y^*_t = \left( \frac{\phi_i}{n} \right)^{\theta_i} \left( 1 - \frac{\sum_j \phi_j^*}{n} \right)^{(1-\theta_i)} \omega_0^{\gamma^t} \left( 1 - \frac{\sum_j \phi_j}{n} \right) A^{1-\gamma^t}. \] (42)

These paths may be compared to the BAU equilibrium. Iterating on the equilibrium law of motion, one derives the time path of the carbon stock as

\[ \omega^*(\omega_0, \theta^t) = \omega_0^{\gamma^t} A^{1-\gamma^t} \prod_{\tau=1}^t (1 - E_{t-\tau}^*(\theta_{t-\tau})) \gamma^t \] (43)

A country’s output path in the BAU equilibrium is given by

\[ y^*_t(\omega_0, \theta^t) = \left( \frac{\phi_i}{1 - \sum_j \phi_{jt}} \right)^{\theta_{it}} \left( 1 - \frac{\sum_j \phi_{jt}}{1 - \sum_j \phi_{jt}} \right)^{(1-\theta_{it})} \omega_0^{\gamma^t} A^{1-\gamma^t} \prod_{\tau=1}^t \left( 1 - \frac{\sum_j \phi_{jt-t-\tau}}{1 - \sum_j \phi_{jt-t-\tau}} \right)^\gamma. \] (44)
Comparing the BAU in (44) with the optimal output in (40). We see that $y_{it}^* < y_{it}^\circ$ iff

$$
\left( \frac{\phi_{it}}{1 - \phi_{it}} \right)^{\theta_{it}} \left( 1 - \sum_j \left( \frac{\phi_{jt}}{1 - \phi_{jt}} \right)^{(1-\theta_{it})} \prod_{\tau=1}^t \left( 1 - \frac{\sum_j \phi_{jt-\tau}}{1 + \sum_j \phi_{jt-\tau}} \right) \right) < \left( \frac{\phi_{it}^\circ}{n} \right)^{\theta_{it}} \left( 1 - \sum_j \frac{\phi_{jt}}{n} \right)^{(1-\theta_{it})} \prod_{\tau=1}^t \left( 1 - \frac{\sum_j \phi_{jt-\tau}}{1 + \sum_j \phi_{jt-\tau}} \right) \gamma^\tau.
$$

In order to evaluate the relative growth in output paths, we compare:

$$
\prod_{\tau=1}^t \left( 1 - \frac{\sum_j \phi_{jt-\tau}}{1 + \sum_j \phi_{jt-\tau}} \right)^{\gamma^\tau} < \prod_{\tau=1}^t \left( 1 - \frac{\sum_j \phi_{jt-\tau}}{n} \right)^{\gamma^\tau}
$$

which holds due to the fact that the aggregate extraction rate is larger (hence conservation rate is smaller) in the MPE. Moreover the relative difference

$$
\prod_{\tau=1}^t \left( 1 - \frac{\sum_j \phi_{jt-\tau}}{n} \right)^{\gamma^\tau} / \prod_{\tau=1}^t \left( 1 - \frac{\sum_j \phi_{jt-\tau}}{1 + \sum_j \phi_{jt-\tau}} \right)^{\gamma^\tau}
$$

is increasing as time passes. Hence, both the expected ratio $E_{y_{it}^* / y_{it}^\circ}$ and the expected difference $E[y_{it}^\circ - y_{it}^*]$ are increasing in $t$.

\textbf{Proof of Theorem 5.} It suffices to show that the planner’s solution admits a finite tipping in the worst case: $\theta_t = 1$. In an economy restricted to $\theta_t = 1$, the policy tipping point is defined by the unstable fixed point solution to $\omega_t = \omega^\circ(\omega_t, 1; b)$ or

$$
\left( \frac{1}{1 - E^\circ(\omega_t, 1; b)} \left[ \left( \frac{\omega_t}{A} \right)^{1/\gamma} + b \right] - \omega_t \right) = 0 \quad (45)
$$

In fact, a finite tipping point exists if we can show that (45) has any solution, stable or unstable. From the planner’s solution, it follows that

$$
E^\circ(\omega_t, 1; b) = \frac{1}{1 + G^\circ(\omega_t, 1; b)}.
$$

Notice that this expression does not vary in $n$. Equation (45) then becomes

$$
H(\omega_t, b) \equiv \left( \frac{1 + G^\circ(\omega_t, 1; b)}{G^\circ(\omega_t, 1; b)} \left[ \left( \frac{\omega_t}{A} \right)^{1/\gamma} + b \right] - \omega_t \right) = 0 \quad (46)
$$
To verify that this equation has a solution, observe that $G(\omega_t, 1; b) \to 0$ as $\omega_t \to 0$ while $G(\omega_t, 1; b) \to G(\omega_t, 1; 0) = \frac{A\delta \gamma}{1-Ab\gamma}$ as $\omega_t \to \infty$. These limits imply $H(\omega_t, b) \to \infty$ as $\omega \to 0$ and $H(\omega_t, b) \to H(\omega_t, 0) < \omega_t$ as $\omega_t \to \infty$. The Intermediate Value Theorem immediately implies the existence of a solution to (46). Consequently, a finite policy tipping point exists, concluding the proof of this theorem.
